[1] We interpret observations of trace-gases from three satellite platforms to provide top-down constraints on the production of NO by lightning. The space-based observations are tropospheric NO₂ columns from SCIAMACHY, tropospheric O₃ columns from OMI and MLS, and upper tropospheric HNO₃ from ACE-FTS. A global chemical transport model (GEOS-Chem) is used to identify locations and time periods in which lightning would be expected to dominate the trace gas observations. The satellite observations are sampled at those locations and time periods. All three observations exhibit a maximum in the tropical Atlantic region and a minimum in the tropical Pacific. This wave-1 pattern is driven by injection of lightning NO into the upper troposphere over the tropical continents, followed by photochemical production of NO₂, HNO₃, and O₃ during transport. Lightning produces a broad enhancement over the tropical Atlantic and Africa of $2\text{--}6 \times 10^{14}$ molecules NO₂ cm⁻², 4×10^{17} molecules O₃ cm⁻² (15 Dobson Units), and 125 pptv of upper tropospheric HNO₃. The lightning background is 25–50% weaker over the tropical Pacific. A global source of 6 ± 2 Tg N yr⁻¹ from lightning in the model best represents the satellite observations of tropospheric NO₂, O₃, and HNO₃.

1. Introduction

[2] Nitrogen oxide radicals (NO_x ≡ NO + NO₂) originating from combustion, lightning, and soils largely control tropospheric O₃ production [Kasibhatla *et al.*, 1991; Penner *et al.*, 1991; Murphy *et al.*, 1993; Jacob *et al.*, 1996]. Lightning remains the most uncertain source of NO_x [Lee *et al.*, 1997]. Most estimates of the global lightning NO_x source have employed a bottom-up approach based on estimates of global flash rates and the number of molecules of NO produced per flash [Price *et al.*, 1997a; Labrador *et al.*, 2005]. Top-down constraints based on satellite observations of trace gases could reduce considerably this uncertainty.

[3] Table 1 contains recent estimates of global lightning NO_x production. Global estimates vary by more than an order of magnitude over 1–20 Tg N yr⁻¹. Flash rates explain only a small fraction of this uncertainty. Recent estimates of global flash rates derived from space-based

measurements from the Optical Transient Detector (OTD) are 44 ± 5 flashes s⁻¹ [Christian *et al.*, 2003], 50–75% of earlier estimates over the last decade. The remaining uncertainty in global estimates from the bottom-up approach arises from the production of NO/flash, for which recent values vary by an order of magnitude, in part reflecting spatial variation in the frequency [Boccippio *et al.*, 2001] and uncertainty in the relative yield [Ridley *et al.*, 2005] of cloud-ground (CG) and intracloud (IC) flashes.

[4] Levy *et al.* [1996] introduced an alternative top-down approach of comparing airborne observations of NO_x and NO_y with a global model simulation and found that this approach yielded a tight constraint on the lightning NO_x source. Boersma *et al.* [2005] extended their method using satellite measurements of tropospheric NO₂ columns from the Global Ozone Monitoring Instrument (GOME). We develop the top-down approach here using global observations of tropospheric NO₂ columns from the Scanning Imaging Absorption Spectrometer for Atmospheric Cartography (SCIAMACHY) satellite instrument [Bovensmann *et al.*, 1999], tropospheric O₃ columns from the Ozone Monitoring Instrument (OMI) [Levelt *et al.*, 2006] and Microwave Limb Sounder (MLS) [Waters *et al.*, 2006] instruments, and upper tropospheric HNO₃ measurements from the Atmospheric Chemistry Experiment Fourier Transform Spectrometer (ACE-FTS) [Bernath *et al.*, 2005]. These multiple species provide three independent constraints on the lightning NO_x source.

[5] A major challenge in interpreting satellite observations of a tropospheric column is ambiguity in the altitude of the gas. Surface sources and free tropospheric sources both

^bRepresents the weighted average for intercloud and cloud-ground flashes.

contribute to column enhancements. Figure 1 shows a current estimate of the distribution of NO_x production by lightning and other sources. Most regions with a substantial lightning NO_x source also contain considerable emissions from other sources, confounding a simple correlation between the column observation and lightning flashes. However, one major difference between the production of NO_x from lightning and other sources is their altitude. Simulations with cloud resolving models suggest that most lightning NO_x is deposited above 7 km [Pickering *et al.*, 1998; Skamarock *et al.*, 2003] where the lifetimes of NO_x, HNO₃, and O₃ are 5–10 times longer than in the lower troposphere. In the tropics, convection of NO_x from surface sources is expected to make a minor contribution to upper tropospheric NO_x compared with lightning NO_x emissions [Levy *et al.*, 1999]. Lightning NO_x would be expected to influence a much broader region than surface sources [Lamarque *et al.*, 1996]. An upper tropospheric air mass will be advected along a different trajectory than a lower tropospheric air-

mass that is influenced by surface emissions. Boersma *et al.* [2005] introduced the idea of a masking scheme to extract the lightning signal by minimizing the interference of surface NO_x sources on satellite observations.

[6] In this work we use a global chemical transport model (GEOS-Chem) to identify the locations, regions, and species that are dominated by the effects of lightning NO_x. Section 2 introduces the GEOS-Chem model. Section 3 compares the satellite observations of tropospheric NO₂, O₃, and HNO₃ with the model simulation in those regions. Conclusions are in section 4.

2. GEOS-Chem Model

[7] We use the GEOS-Chem global three-dimensional (3-D) chemical transport model to account for the photochemical evolution and transport of NO_x. The simulation is driven by assimilated meteorological data from the Goddard Earth Observing System (GEOS-4) at the NASA Global

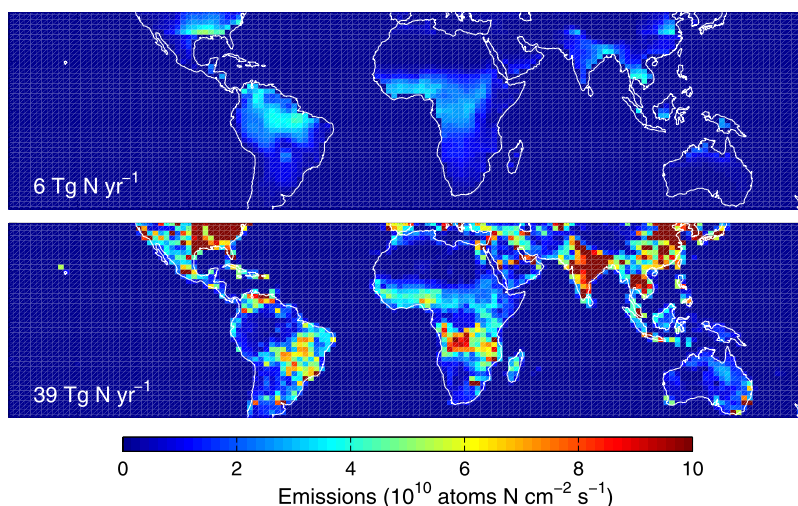

Figure 1. Annual mean NO_x emissions used in the standard GEOS-Chem simulation from (top) lightning and (bottom) all other sources including fossil fuel combustion, biomass burning, biofuels, and soils.

Modeling and Assimilation Office (GMAO). We use here version 7-03-03 of GEOS-Chem (www-as.harvard.edu/chemistry/trop/geos) with additional midlatitude lightning NO_x as described below. The GEOS-Chem model includes a detailed simulation of tropospheric ozone-NO_x-hydrocarbon chemistry as well as of aerosols and their precursors. The ozone-NO_x-hydrocarbon simulation was first described by *Bey et al.* [2001] with updates by *Fiore et al.* [2002] and *Martin et al.* [2002b, 2003b]. The model presently includes sulfate, nitrate, ammonium, black carbon, organic carbon, mineral dust, and sea salt [*Park et al.*, 2003; *Park et al.*, 2004; *Alexander et al.*, 2005; *Fairlie et al.*, 2006]. The aerosol and gaseous simulations are coupled through formation of sulfate and nitrate, HNO₃(g)/NO₃⁻ partitioning of total inorganic nitrate, heterogeneous chemistry on aerosols [*Jacob*, 2000; *Evans and Jacob*, 2005], and aerosol effects on photolysis rates [*Martin et al.*, 2003b].

[8] Figure 1 shows the annual global distribution of NO_x emissions in GEOS-Chem for all sources. Anthropogenic NO_x emissions are based on the Global Emission Inventory Activity (GEIA) [*Benkovitz et al.*, 1996] as described by *Bey et al.* [2001]. Soil NO_x emissions are computed using a modified version of the algorithm of *Yienger and Levy* [1995] with the canopy reduction factors described by *Y. Wang et al.* [1998]. The biomass burning inventory is seasonally varying and is based on satellite observations of fires over 1996–2000 from the Along Track Scanning Radiometer (ATSR) as derived by *Duncan et al.* [2003]. Emissions of lightning NO_x are linked to deep convection following the parameterization of *Price and Rind* [1992] with vertical profiles from *Pickering et al.* [1998] as implemented by *Y. Wang et al.* [1998]. The midlatitude lightning NO_x source is increased here by a factor of four to 1.6 Tg N yr⁻¹ following *Hudman et al.* [2007] and *Martin et al.* [2006] to correct a model bias in simulated NO_x versus INTEX-A aircraft observations, to be consistent with NO production per flash estimates from recent cloud-scale modeling [*DeCaria et al.*, 2005; *Pickering et al.*, 2006], and to account for recent observational evidence that midlatitude lightning may produce more NO per flash than tropical lightning [*Huntrieser et al.*, 2006]. The model chemical fields have been evaluated versus in situ and satellite observations throughout the tropics [*Bey et al.*, 2001; *Chandra et al.*, 2002; *Martin et al.*, 2002b; *Chandra et al.*, 2003; *Martin et al.*, 2003a; *Jaeglé et al.*, 2005; *Kim et al.*, 2005; *Folkins et al.*, 2006; *Liu et al.*, 2006; *Sauvage et al.*, 2007a].

[9] We conduct eight sensitivity simulations with variable lightning source strength, or with NO_x emissions excluded from either biomass burning or soils to examine the effect of these sources. Sensitivity simulations are conducted over May 2004 to April 2005, following a 4-month spinup. Two additional sensitivity studies are used to assess the robustness of the conclusions to spatial variation in the lightning source. Estimates of the relative vertical distribution of lightning NO_x is affected by uncertainty in the NO_x production per flash for intracloud (P_{IC}) and cloud-ground (P_{CG}) flashes. The vertical profiles from *Pickering et al.* [1998] used in the standard simulation were determined for a P_{IC}/P_{CG} ratio of 0.1, based on the work of *Price et al.* [1997a]. There is evidence for a P_{IC}/P_{CG} ratio of 0.5–1 [*Gallardo and Cooray*, 1996; *DeCaria et al.*, 2000; *Zhang et al.*, 2003; *Fehr et al.*, 2004; *DeCaria et al.*, 2005; *Ott et*

al., 2007]. One sensitivity study uses a P_{IC}/P_{CG} ratio of 0.75 in which the additional NO_x from intracloud flashes is distributed within the cloud anvil.

[10] *Allen and Pickering* [2002] found that the *Price and Rind* [1992] lightning parameterization does not fully capture the observed distribution of lightning activity. We conduct another sensitivity study in which the spatial distribution of lightning NO_x production is rescaled to match 10 years of seasonally varying observations of lightning flashes from the OTD and the Lightning Imaging Sensor (LIS) as implemented by *Sauvage et al.* [2007a].

3. Top-Down Constraints on Lightning NO_x Emissions

[11] Satellite retrievals of tropospheric NO₂ columns, tropospheric O₃ columns, and upper tropospheric HNO₃ provide three independent constraints on the production of NO from lightning. We examine each species in turn.

3.1. Analysis of Tropospheric NO₂ Columns

[12] The SCIAMACHY instrument on board the ENVISAT satellite provides the capability for global retrieval of atmospheric NO₂ columns through observation of global backscatter [*Bovensmann et al.*, 1999]. The satellite was launched in March 2002 into a Sun-synchronous orbit, crossing the equator at about 1000 LT in the descending node. The SCIAMACHY instrument observes the atmosphere in the nadir view with a typical surface spatial resolution of 30 km along track by 60 km across track. Global coverage is achieved every 6 days.

[13] We use cloud-filtered (cloud radiance fraction <0.5) tropospheric NO₂ columns retrieved by *Martin et al.* [2006] for May 2003 to April 2005. The retrieval involves a spectral fit over 429–452 nm to produce total slant columns, removal of stratospheric NO₂ columns using SCIAMACHY observations over the Pacific, and an air mass factor calculation to correct for atmospheric scattering. The data have been validated with in situ airborne observations of NO₂ over and downwind of North America as part of the ICARTT campaign. The retrieval uncertainty is ±(5 × 10¹⁴ molecules cm⁻² + 30%) for cloud-filtered scenes with larger uncertainty for cloudy scenes. The omission of cloudy scenes is of little consequence for our analysis due to the long upper tropospheric NO_x lifetime of 5–10 days as inferred by *Jaeglé et al.* [1998].

[14] Figure 2 shows a seasonal average of cloud-filtered SCIAMACHY tropospheric NO₂ columns. Tropospheric NO₂ columns are strongly correlated with surface emissions [*Martin et al.*, 2003a; *Toenges-Schuller et al.*, 2006]. NO₂ columns are largest in winter over industrial regions due to seasonal variation in the NO_x lifetime [*Velders et al.*, 2001]. The seasonal variation of tropical NO₂ columns reflects biomass burning and soil NO_x emissions [*Jaeglé et al.*, 2005]. Identification of a lightning signal in satellite observations of NO₂ columns is complicated by the higher measurement sensitivity to NO_x in the lower troposphere than in the upper troposphere [*Martin et al.*, 2002a], resulting from the factor of 25 increase in the NO/NO₂ ratio from the surface to the tropopause [*Bradshaw et al.*, 1999] that is driven by the temperature dependence of the NO + O₃ reaction.

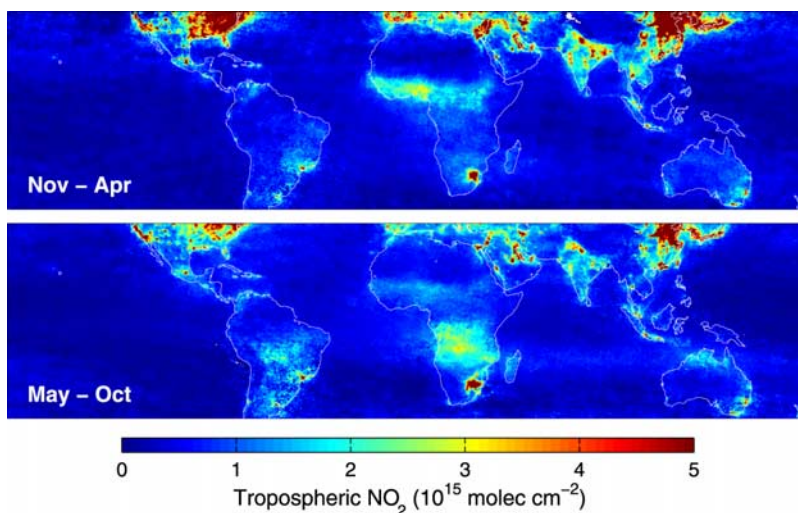

Figure 2. Mean tropospheric NO₂ columns retrieved from the SCIAMACHY satellite instrument for (top) November–April and (bottom) May–October. Scenes where clouds or snow dominate solar backscatter have been excluded from the average to reduce retrieval uncertainty. Data from *Martin et al.* [2006].

[15] The interpretation of satellite observations of tropospheric columns warrants clarification of the tropical tropopause. The level of zero radiative heating occurs at 14–15 km, above which air either mixes with the extratropical stratosphere or slowly ascends through the

thermal tropopause at 16–17 km and into the tropical stratosphere [*Highwood and Hoskins, 1998; Folkins et al., 1999*]. We refer to the tropopause as the thermal tropopause and to tropospheric columns as values below the thermal tropopause.

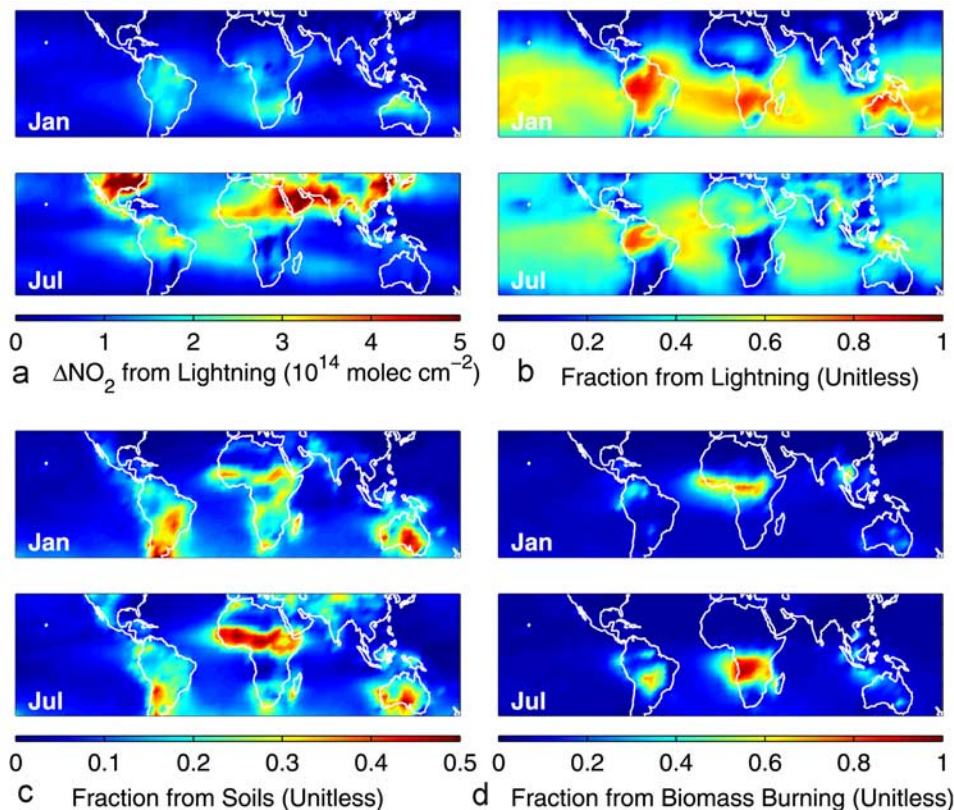

Figure 3. Sensitivity of simulated tropospheric NO₂ columns to NO_x emissions from lightning, soils, and biomass burning for January and July. (a) Shown is the NO₂ column due to lightning NO_x emissions as determined by the difference between the standard simulation and a simulation that excludes lightning NO_x emissions. Also shown is the fraction of the simulated tropospheric NO₂ column from (b) lightning, (c) soils, and (d) biomass burning.

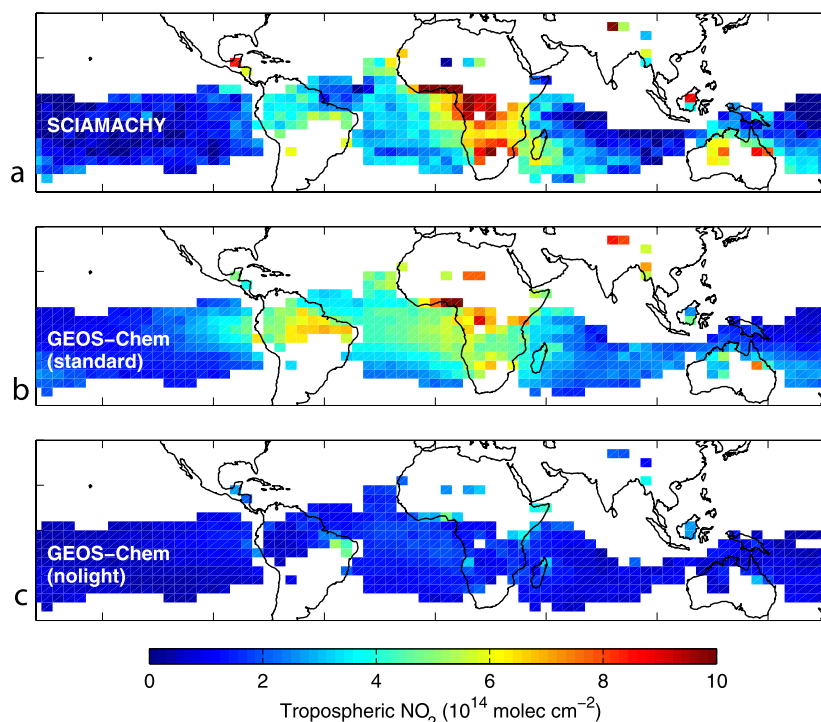

Figure 4. Annual average of tropospheric NO₂ columns at locations and times in which more than 60% of the simulated NO₂ column is from lightning, and less than 25% of the simulated NO₂ column is from any surface NO_x source (soils, biomass burning, fossil fuels, or biofuel). White areas indicate regions where these thresholds were not met. Shown are (a) data retrieved from the SCIAMACHY satellite instrument, (b) the standard simulation with 6 Tg N yr⁻¹ from lightning, and (c) a simulation without lightning NO_x emissions.

[16] Given the strong relationship of tropospheric NO₂ columns with surface emissions, we use the GEOS-Chem model for guidance in identifying locations where a lightning influence would be expected. Figure 3 shows the sensitivity of tropospheric NO₂ columns to NO_x emissions from either lightning, soils, or biomass burning as determined from the difference between the standard simulation and sensitivity simulations that exclude either source. Figure 3a shows that the largest lightning-induced enhancements of the tropospheric NO₂ column are found over and downwind of active convective regions. The maximum monthly mean enhancements are comparable to the SCIAMACHY retrieval uncertainty.

[17] Figure 3b shows the fraction of the NO₂ column from lightning. This fraction is anticorrelated ($r = -0.49$) with the simulated tropical tropospheric NO₂ column, reflecting the greater sensitivity of SCIAMACHY to NO_x in the lower troposphere than in the upper troposphere. The largest relative contributions from lightning are found over convective regions with negligible surface sources. Lightning has the broadest relative influence during January–April when flashes are most frequent in the Southern Hemisphere and when biomass burning is largely confined to the Northern Hemisphere. Lightning makes the weakest relative contribution during July–October when lightning is active in the Northern Hemisphere where there are numerous anthropogenic sources.

[18] Figures 3c and 3d show the fraction of the tropospheric NO₂ column from soil and biomass burning emis-

sions. The largest fractions from soils are found over tropical savannas during the wet season. Jaeglé *et al.* [2004] attributed GOME observations of tropospheric NO₂ column enhancements over northern Africa to rain-induced emissions of NO from soils. A large contribution from biomass burning of more than 50% is found over northern equatorial Africa during January and over central Africa during July. Soil and biomass burning emissions make a small contribution (typically <25%) to tropospheric NO₂ columns over oceans. The sum of the fractional contributions from these sources can exceed 100% due to nonlinearities.

[19] We sample the SCIAMACHY data at locations and months in which GEOS-Chem simulations indicate that more than 60% of the NO₂ column is from lightning, and less than 25% of the NO₂ column originates from any surface NO_x source (soils, biomass burning, fossil fuel, or biofuel). These thresholds retain 15% of the tropical SCIAMACHY data. Most land regions are excluded by these thresholds, since surface NO_x sources often dominate the NO₂ column over land.

[20] Figure 4a shows the annual average of the filtered SCIAMACHY tropospheric NO₂ columns. The largest enhancements are found over central Africa reflecting intense lightning activity [Christian *et al.*, 2003]. A broad enhancement of $3\text{--}6 \times 10^{14}$ molecules cm⁻² is evident over the tropical Atlantic and Indian Oceans, reflecting upper tropospheric transport from continental regions. Lightning is the dominant source of reactive nitrogen transported into the tropical Atlantic in a numerical simulation by Moxim

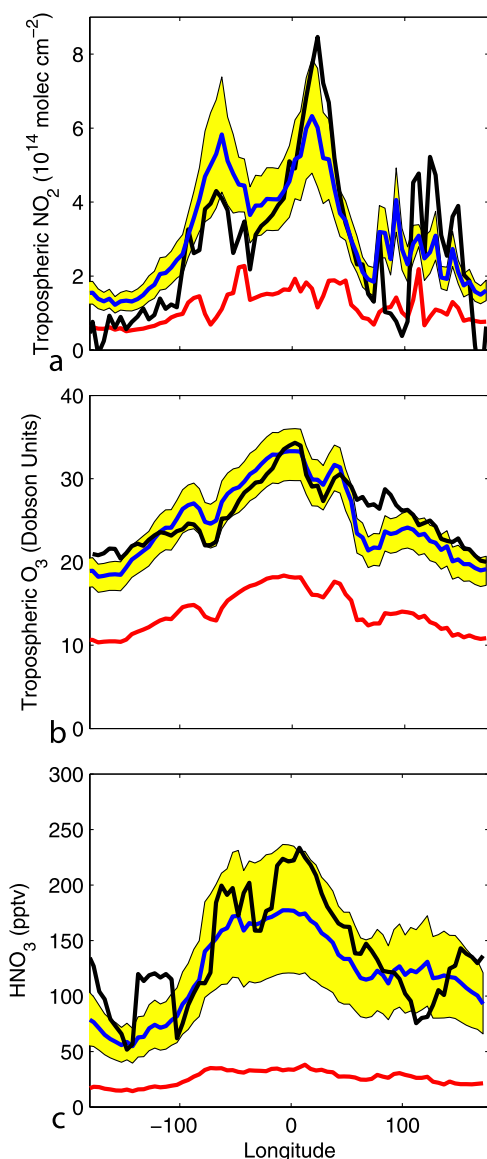

Figure 5. Meridional average of annual mean trace gas concentrations for locations and months that are dominated by the effects lightning NO_x. Shown are (a) tropospheric NO₂ columns for locations and months in which more than 60% of the tropospheric NO₂ column is from lightning, and less than 25% of the NO₂ column from any surface NO_x source, (b) the tropospheric O₃ column averaged over locations and months in which more than 40% of the simulated concentrations are from lightning NO_x, and (c) the HNO₃ mixing ratio between 200 and 350 hPa averaged over locations and months in which more than 60% of the simulated concentrations are from lightning NO_x. Black lines indicate satellite observations. Blue lines indicate the standard simulation with 6 Tg N yr⁻¹ from lightning. The boundaries of the yellow shaded regions indicate sensitivity simulations of 4 and 8 Tg N yr⁻¹ from lightning. Red lines indicate the simulation without lightning NO_x emissions.

and Levy [2000]. Previous analyses of tropospheric NO₂ columns retrieved from GOME also found evidence of lightning NO_x over the tropical Atlantic [Richter and Burrows, 2002; Edwards et al., 2003; Boersma et al., 2005].

[21] Figure 4b shows the annual average of simulated tropospheric NO₂ columns, sampled at the same time and location as the SCIAMACHY measurements. The modeled NO₂ columns are broadly consistent with the SCIAMACHY data ($r = 0.75$, $n = 1937$, bias = 8%). The simulation also exhibits a broad maximum over the tropical Atlantic Ocean and a broad minimum over the tropical Pacific Ocean. The simulation overestimates the lightning signal over South America and underestimates the lightning signal over Africa, common problems for models using the Price and Rind [1992] parameterization [Allen and Pickering, 2002]. This bias is reduced in the sensitivity simulation in which lightning flashes are rescaled to the OTD/LIS observations.

[22] Figure 4c shows the annual average of tropospheric NO₂ columns in the simulation without lightning NO_x emissions. Tropospheric NO₂ columns in this simulation are biased low by 60% with respect to the SCIAMACHY data. Comparison with Figure 4b reveals that lightning largely explains the broad wave-1 pattern in the SCIAMACHY NO₂ columns.

[23] Figure 5a compares the meridional average of all the tropospheric NO₂ columns in Figure 4. Both the SCIAMACHY NO₂ columns and the standard simulation show enhancements in the tropical Atlantic, relative to the tropical Pacific. No such pattern is found in the simulation without lightning NO_x emissions. Emissions of 4–8 Tg N yr⁻¹ would best represent the SCIAMACHY data over most of the tropics. The magnitude of the annual mean lightning signal in the tropospheric NO₂ observations is about $2\text{--}6 \times 10^{14}$ molecules cm⁻², comparable to the local uncertainty of about 5×10^{14} molecules cm⁻² in the SCIAMACHY tropospheric NO₂ retrievals. However, it is likely that the retrieval error is reduced for the spatial and temporal mean examined here.

3.2. Analysis of Tropospheric Ozone Columns

[24] The OMI and MLS instruments were launched in July 2004 on board the Aura spacecraft into a polar Sun-synchronous orbit [Schoeberl et al., 2004]. OMI is a nadir-scanning instrument that detects backscattered solar radiance over 270–500 nm to measure column O₃ with near global coverage at a resolution of 13 km × 24 km at nadir [Levell et al., 2006]. The EOS MLS instrument is a thermal-emission microwave limb sounder that measures vertical profiles of mesospheric, stratospheric, and upper tropospheric O₃ from limb scans ahead of the Aura satellite [Froidevaux et al., 2006; Waters et al., 2006]. Ziemke et al. [2006] combined measurements from both instruments to retrieve daily tropospheric O₃ columns with a measurement uncertainty of 5 Dobson Units (DU) as determined by comparison with ozonesondes.

[25] Figure 6 shows tropospheric O₃ columns retrieved from the OMI and MLS instruments for January and July. A persistent wave-1 pattern is found in the southern tropics, with a maximum in the tropical Atlantic and a minimum in the tropical Pacific throughout the year [Fishman et al., 1990; Shiotani, 1992; Ziemke et al., 1996; Hudson and Thompson, 1998; Thompson et al., 2003; Sauvage et al., 2006]. The minimum in the tropical Pacific reflects the rapid destruction of O₃ in the marine boundary layer [Piotrowicz et al., 1991; Kley et al., 1996] coupled with

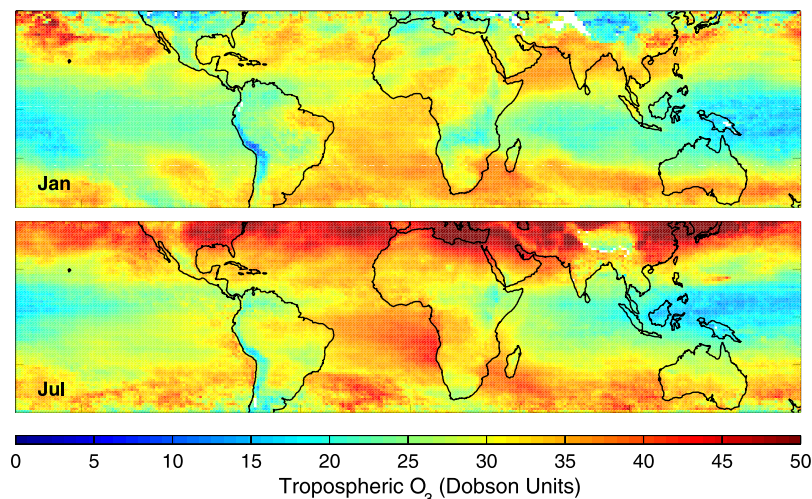

Figure 6. Tropospheric ozone columns retrieved from the Ozone Monitoring Instrument (OMI) and Microwave Limb Sounder (MLS) for (top) January 2005 and (bottom) July 2005. Data from Ziemke *et al.* [2006].

the negative tendency of deep convection on the O₃ column [Lelieveld and Crutzen, 1994]. The persistent maximum over the tropical Atlantic reflects the integrated effect on O₃ of lightning emissions over the tropical continents [Jacob *et al.*, 1996; Martin *et al.*, 2002b; Sauvage *et al.*, 2007b], coupled with seasonal enhancements from biomass burning [Thompson *et al.*, 1996; Jenkins *et al.*, 1997]. The enhancement in the northern hemisphere during July is driven by photochemical production from anthropogenic emissions [Fishman and Brackett, 1997]. Enhancements at $\pm 30^\circ$ are due to a combination of subsidence from the stratosphere and photochemical production [Li *et al.*, 2002; Jing *et al.*, 2005].

[26] Figure 7 shows the simulated sensitivity of tropospheric O₃ columns to lightning NO_x emissions. Lightning makes a broad contribution to tropospheric O₃ columns throughout the tropics reflecting the upper tropospheric O₃ lifetime of several weeks. A particularly large O₃ column enhancement from lightning is apparent during January in the southern tropical Atlantic, contributing to the north-south oceanic gradient that was highlighted by Thompson

et al. [2000]. Weaker enhancements from lightning are found over the Middle East during July [Li *et al.*, 2001] and in the subsiding branches of the Hadley Circulation near $\pm 30^\circ$. Lightning makes a smaller relative contribution to the tropospheric O₃ column during July when biomass burning emissions are more abundant in the southern hemisphere and when lightning is predominantly in the northern hemisphere where anthropogenic sources dominate.

[27] Figure 8a shows the annual average over September 2004 to August 2005 of the OMI/MLS tropospheric O₃ columns at locations and times in which more than 40% of the simulated column is from lightning. This threshold retains 15% of the tropical OMI/MLS observations. Only 0.1% of the remaining observations would be affected by an additional threshold of 25% on the O₃ column fraction from surface sources. Figure 8b shows the annual average of the standard simulation sampled at the same locations and months as the OMI/MLS data. There is a high degree of consistency between the simulated and satellite data ($r = 0.85$, $n = 1953$, bias = -1%). Figure 8c shows tropospheric

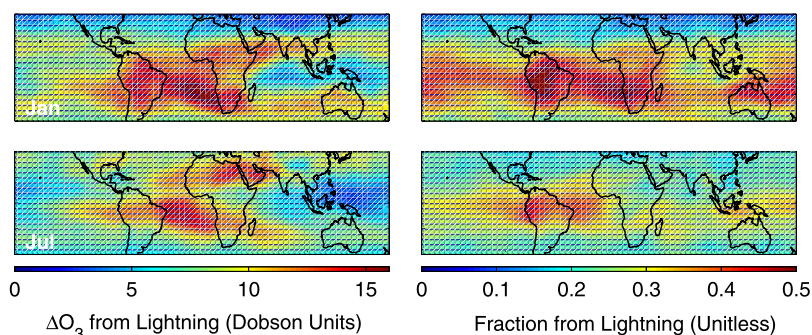

Figure 7. Sensitivity of tropospheric ozone columns to lightning NO_x emissions for (top) January and (bottom) July. The left column indicates the tropospheric ozone column due to lightning NO_x emissions as determined by the difference between the standard simulation and a simulation that excludes lightning NO_x emissions. The right column indicates the corresponding fraction of the tropospheric ozone column from lightning NO_x emissions.

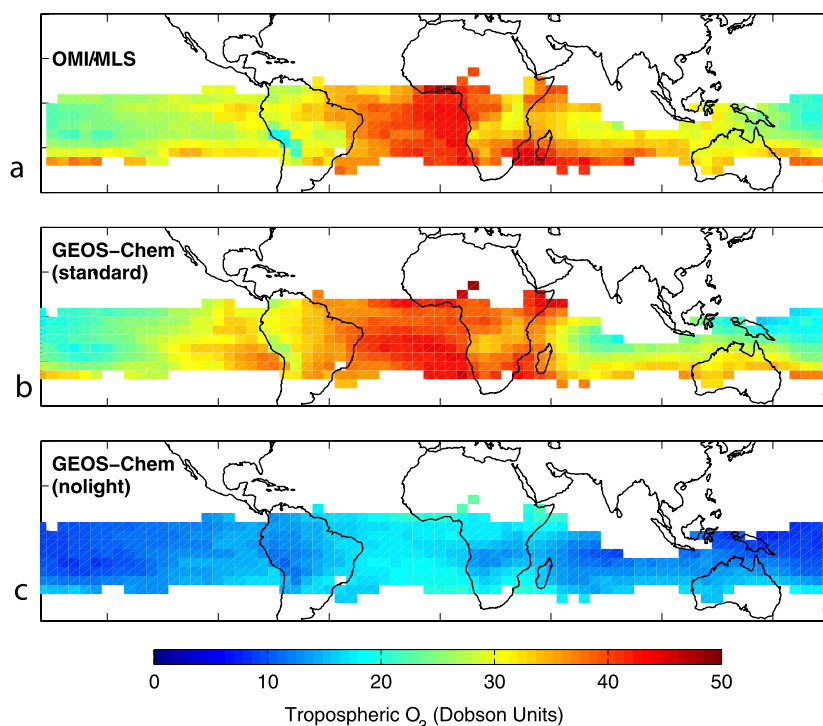

Figure 8. Annual average of tropospheric ozone columns at locations and times in which GEOS-Chem simulations yield more than 40% of the tropospheric ozone column from lightning. White areas indicate regions where these thresholds were not met. Shown are (a) data determined from the OMI and MLS satellite instruments, (b) the standard simulation with 6 Tg N yr⁻¹ from lightning, and (c) a simulation without lightning NO_x emissions.

O₃ columns for the simulation without lightning NO_x emissions, revealing a large negative bias of 45% versus the OMI/MLS observations. The magnitude of the lightning signal of 10–15 DU, as determined by the difference between the standard simulation and the simulation without lightning, is 2–3 times greater than the retrieval uncertainty.

[28] Figure 5b shows the meridional average of the tropospheric O₃ columns in Figure 8. Lightning NO_x production

of 4–6 Tg N yr⁻¹ would best represent the OMI/MLS observations in the Atlantic, while a rate of 6–8 Tg N yr⁻¹ would best represent observations in the Pacific.

3.3. Analysis of Upper Tropospheric HNO₃

[29] The ACE-FTS instrument [Bernath *et al.*, 2005] was launched on board the SCISAT-1 spacecraft into a low Earth orbit (altitude 650 km, inclination 74°) in August 2003.

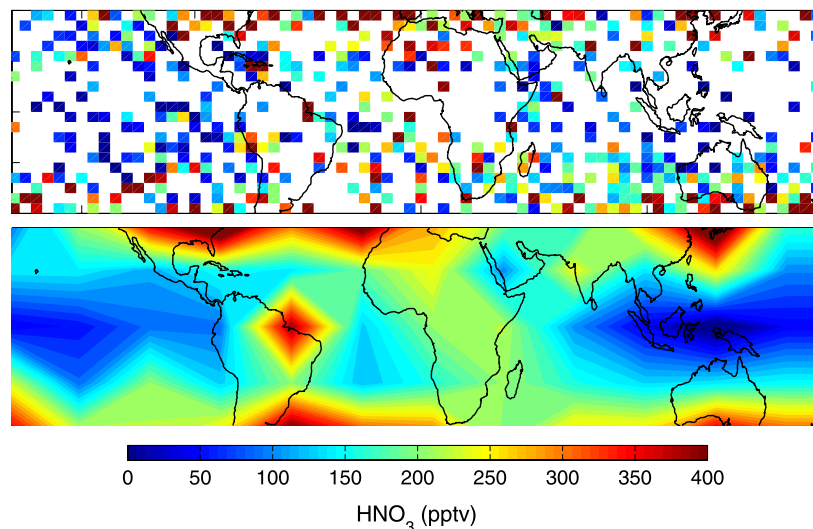

Figure 9. Mean HNO₃ retrieved from the ACE-FTS satellite instrument over 200–350 hPa for March 2004 to February 2006 inclusive. The data are binned onto a 4° latitude by 5° longitude grid in the top panel and onto a 20° latitude by 30° longitude grid in the bottom panel. Data from Boone *et al.* [2005].

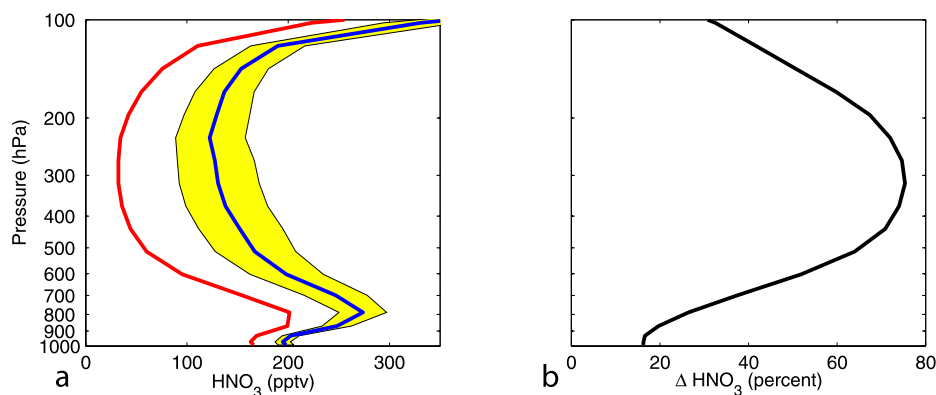

Figure 10. Vertically resolved sensitivity of the tropical (30°S–30°N) HNO₃ concentration to NO_x emissions from lightning, showing (a) the annual mean tropical HNO₃ mixing ratio. The blue line indicates the standard simulation. The boundaries of the yellow shaded region indicate sensitivity simulations of 4 and 8 Tg N yr⁻¹ from lightning. The red line indicates simulated values in the simulation without lightning NO_x emissions. Also shown is (b) the fraction of HNO₃ from lightning as determined by the difference between the standard simulation and a simulation without lightning NO_x emissions.

The ACE-FTS instrument is a high spectral resolution (0.02 cm⁻¹) Fourier Transform Spectrometer operating over 750–4400 cm⁻¹ (2.2–13.3 μm). From the ACE-FTS solar occultation measurements, HNO₃ profiles are retrieved with an altitude resolution of 3–4 km [Boone *et al.*, 2005]. The retrievals employ HNO₃ spectral features in the ranges 860–910 cm⁻¹ and 1690–1730 cm⁻¹. The typical measurement uncertainty in the upper troposphere is 35 pptv. The data used here are research retrievals for HNO₃, a refinement of the version 2.2 ACE-FTS data set.

[30] Figure 9 shows the average of HNO₃ concentrations over 200–350 hPa from ACE-FTS for March 2004 to February 2006 inclusive. Enhancements are found poleward of 25° due to a combination of seasonally varying tropospheric and stratospheric sources. Consistently low values are seen over the Pacific Ocean. As with NO₂ and O₃, we use the GEOS-Chem model to provide insight into the processes affecting the HNO₃ distribution.

[31] We first examine the vertical sensitivity of HNO₃ to lightning NO_x emissions. Figure 10a shows HNO₃ concentrations for simulations with and without lightning. A broad minimum in the tropical upper troposphere has been attributed to convective outflow of air depleted of this highly soluble

species [Folkins *et al.*, 2006]. The increase in HNO₃ with decreasing pressure represents an increasing stratospheric contribution, while the increase toward the surface is driven by photochemical production of HNO₃ during subsidence. The role of surface NO_x sources increases markedly below 600 hPa. Figure 10b shows that oxidation of lightning NO_x explains nearly 80% of HNO₃ concentrations over 200–350 hPa. We focus our attention on this region.

[32] Figure 11 shows the calculated horizontal sensitivity of HNO₃ concentrations to lightning NO_x. The left column of Figure 11 indicates pronounced enhancements over and downwind of convective regions, especially in the southern tropics during January. The right column of Figure 11 indicates that during January lightning NO_x explains 80% of HNO₃ mixing ratios over a broad region south of 25°N, with stratospheric NO_y making a larger contribution further north. During July, stratospheric NO_y plays a more important role at these pressures south of 25°S. Airborne measurements in the upper troposphere provide evidence that HNO₃ increases the relative humidity in low-temperature cirrus clouds [Gao *et al.*, 2004]. The pronounced contribution of lightning to upper tropospheric HNO₃ found here suggests that a hypothesized increase in lightning NO_x

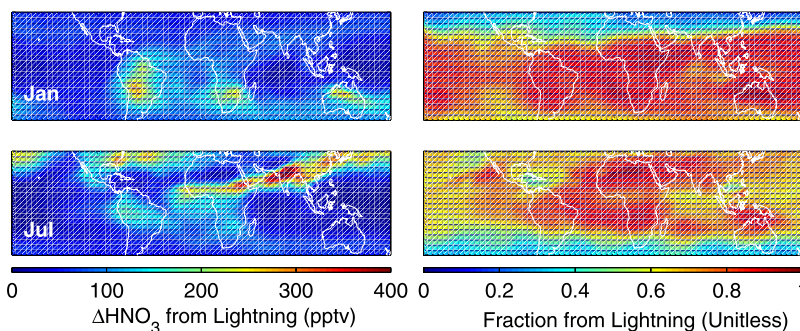

Figure 11. Sensitivity of HNO₃ concentrations over 200–350 hPa to lightning NO_x emissions for (top) January and (bottom) July. The left column shows the HNO₃ mixing ratio due to lightning NO_x, as determined by the difference between the standard simulation and a simulation without lightning NO_x emissions. The right column shows the corresponding fraction of the HNO₃ mixing ratio from lightning.

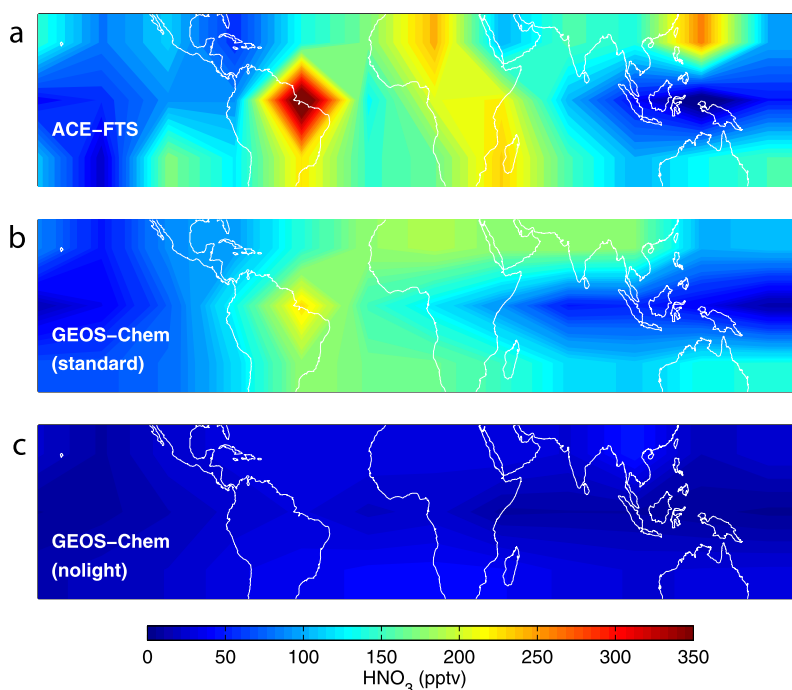

Figure 12. Annual average of the HNO₃ mixing ratio at locations and times in which more than 60% of the simulated HNO₃ concentration is from lightning. Shown are (a) data retrieved from the ACE satellite instrument, (b) the standard simulation with 6 Tg N yr⁻¹ from lightning, and (c) a simulation without lightning NO_x emissions.

emissions from climate change [Price and Rind, 1994] could have implications for upper tropospheric water vapor.

[33] Figure 12 shows the HNO₃ mixing ratio at locations and times in which more than 60% of the simulated HNO₃ is from lightning. This threshold retains 83% of the tropical ACE-FTS measurements while eliminating the seasonally varying stratospheric air poleward of 25°. The measured and simulated HNO₃ mixing ratios in Figures 12a and 12b are generally consistent ($r = 0.75$, $n = 360$, bias = -12%). The simulation underestimates observed upper tropospheric HNO₃ over South America and Africa. However, both the simulation and the observations exhibit a maximum in the tropical Atlantic and a minimum in the tropical Pacific. This wave-1 pattern reflects the frequent injection of HNO₃ depleted air into the upper troposphere of the tropical Pacific, coupled with photochemical production during transport to the tropical Atlantic as part of the Walker circulation. Figure 12c shows that HNO₃ mixing ratios in the simulation without lightning NO_x emissions are only 1/5th of the observations.

[34] Figure 5c shows the meridional average of the upper tropospheric HNO₃ in Figure 12. The simulation with 6 Tg N yr⁻¹ from lightning best represents the ACE-FTS observations over most of the world. The strength of the lightning signal in the observations ranges from a minimum of 50 pptv over the western Pacific Ocean to 200 pptv over the tropical Atlantic, exceeding the typical ACE-FTS measurement precision of 35 pptv.

4. Discussion

[35] On balance, all three measurements yield a top-down estimate on the lightning NO_x source of 4–8 Tg N yr⁻¹,

with 6 Tg N yr⁻¹ being most likely. Potential errors in the simulations used to reach this conclusion are reduced by using three different trace gases with lifetimes ranging from several days for NO_x to several weeks for O₃ and HNO₃. Varying the thresholds used to filter the observations has little effect on the estimate. The sensitivity simulation in which the spatial distribution of lightning flashes is scaled to observations from the OTD and LIS instruments has negligible implications for the top-down estimate for all three trace gases, also supporting the conclusion. Annual mean tropospheric O₃ columns over the regions affected by lightning in the sensitivity simulation with enhanced intracloud lightning exhibit little difference (<1 DU) with the standard simulation, again supporting the conclusion. The small O₃ column enhancement in the simulation with enhanced intracloud lightning reflects compensating changes in upper and lower tropospheric O₃ and in its regional distribution. Sauvage *et al.* [2007a] further discuss the implications of both sensitivity simulations on tropospheric O₃. The weak interannual variation in tropical tropospheric O₃ columns of less than 10% found by Ziemke and Chandra [1999] implies a similarly small interannual variation in the lightning NO_x source.

[36] The global estimate of 6 ± 2 Tg N yr⁻¹ derived here is well within the range of recent estimates in Table 1. Our estimate is also consistent with the value of 5 ± 3 Tg N yr⁻¹ that is used in numerous chemical transport models as summarized by Zhang *et al.* [2003]. A global source strength of less than 4 Tg N yr⁻¹ or greater than 8 Tg N yr⁻¹ would imply gross errors in current simulations of tropospheric O₃ and reactive nitrogen.

[37] The sensitivity simulation with enhanced intracloud lightning NO_x indicates that tropospheric NO₂ columns and

upper tropospheric HNO₃ concentrations could provide insight into the vertical profile of NO_x emissions. Owing to the increasing NO/NO₂ ratio with altitude, tropospheric NO₂ columns in the simulation with enhanced intracloud lightning are about half of those in the standard simulation, well below the local retrieval uncertainty. In contrast, upper tropospheric HNO₃ concentrations in the simulation with enhanced intracloud lightning are 50–100% larger than in the standard simulation. These divergent effects could imply that in the tropics cloud-ground lightning releases more NO_x than intracloud lightning. *Sauvage et al.* [2007a] similarly find that enhanced intracloud lightning NO_x reduces the consistency of simulated O₃ versus measured vertical profiles from aircraft and ozonesondes. However, if enhanced tropical intracloud lightning is appropriate, two possible explanations for the bias in simulated HNO₃ are an underestimate in the GEOS-4 cloud mass flux detrainment profile [Folkens *et al.*, 2006], or the uptake of HNO₃ by ice in the upper troposphere [e.g., Abbatt, 1997; Zondlo *et al.*, 1997]. These coupled issues should be revisited with improved representations of vertical transport, when the existing uncertainty [Ullerstam *et al.*, 2005; von Kuhlmann and Lawrence, 2006] in the ice uptake process is reduced, and when the next generation of vertical profiles of lightning NO_x production become available.

[38] The top-down estimate inferred here is based largely on tropical measurements. Included in this global estimate is a northern midlatitude lightning NO_x source of 1.6 Tg N yr⁻¹ that is based on recent evidence from aircraft, ozonesonde, and satellite observations as part of the ICARTT and STERAO-A campaigns [DeCaria *et al.*, 2005; Cooper *et al.*, 2006; Hudman *et al.*, 2007; Martin *et al.*, 2006; Pickering *et al.*, 2006]. Recent estimates of the number of moles of NO released per flash over Germany are 70–80% of the North American values [Fehr *et al.*, 2004; Ott *et al.*, 2007] that were used for the midlatitude estimate. Future refinement of the midlatitude lightning NO_x source will propagate into the global estimate.

[39] The OMI instrument also provides the capability for retrieval of tropospheric NO₂ columns [e.g. Bucseila *et al.*, 2006]. Unfortunately, the OMI tropospheric NO₂ product was not available to us at the time of this analysis. Future extension of this approach to use tropospheric NO₂ columns from OMI could benefit from its small footprint in the nadir and daily global coverage.

5. Conclusions

[40] We have analyzed space-based observations of tropospheric NO₂ columns from SCIAMACHY over 2003–2005, tropospheric O₃ columns from OMI and MLS over 2004–2005, and upper tropospheric HNO₃ from ACE-FTS over 2004–2006 to provide top-down constraints on lightning NO_x emissions. A global chemical transport model (GEOS-Chem) was used to identify the locations and months in which lightning would be expected to make a significant contribution to each species. The satellite retrievals were sampled at those locations and months for comparison with model simulations using lightning NO_x emissions of different magnitudes. This approach exploits the role of transport and photochemistry in separating the effect of lightning NO_x from surface NO_x sources. Partic-

ular attention was devoted to excluding regions of biomass burning and soil NO_x emissions that could be misinterpreted as a lightning signal in the SCIAMACHY NO₂ columns.

[41] All three filtered satellite datasets revealed a prominent wave-1 pattern with a maximum in the tropical Atlantic and a minimum in the tropical Pacific. The wave-1 pattern is driven by injection of lightning NO into the upper troposphere over the tropical continents, followed by photochemical production of NO₂, HNO₃, and O₃ during transport to the tropical Atlantic as part of the Walker Circulation. The lightning signal over the tropical Atlantic and Africa was $2\text{--}6 \times 10^{14}$ molecules NO₂ cm⁻², 15 Dobson Units of O₃, and 125 pptv HNO₃, as determined by the difference between the standard simulation with 6 Tg N yr⁻¹ from lightning and a simulation without lightning NO_x emissions. The lightning signal over the tropical Pacific was 25–75% weaker.

[42] Sensitivity simulations were conducted with the GEOS-Chem model for lightning NO_x emissions of 0, 4, 6, and 8 Tg N yr⁻¹. The simulations were sampled at the same locations and times as the satellite observations. Comparison of these simulations with the satellite observations reveals that it is very likely that global lightning NO_x emissions are between 4 and 8 Tg N yr⁻¹. Emissions of 6 Tg N yr⁻¹ provide the most consistent representation of the NO₂, HNO₃, and O₃ measurements. This conclusion is robust to scaling the spatial distribution of the simulated lightning NO_x production to flash count observations from the OTD and LIS instruments.

[43] Tropospheric O₃ columns provide a particularly strong constraint on the magnitude of lightning NO_x emissions due to their insensitivity to the relative vertical profile of lightning NO_x production, and due to the large lightning signal of 10–15 DU that is 2–3 times greater than the measurement uncertainty. Tropospheric NO₂ columns and upper tropospheric HNO₃ concentrations provide additional information on the vertical profile of lightning NO_x production. Increasing the altitude of lightning NO_x production reduces the tropospheric NO₂ column by increasing the NO/NO₂ ratio, while increasing the upper tropospheric HNO₃ concentration by reducing convective scavenging. A sensitivity simulation with enhanced intracloud lightning yields NO₂ columns that are half of those in the standard simulation and HNO₃ concentrations that are 50–100% larger than those in the standard simulation.

[44] This analysis could be improved in a number of ways. The lightning signal is comparable to the measurement uncertainty for tropospheric NO₂; a more accurate retrieval of this species would be particularly valuable. The ACE-FTS HNO₃ measurements remain sparse; additional measurements from the Tropospheric Emission Spectrometer (TES), the Microwave Limb Sounder (MLS), or the Interferometric Monitor for Greenhouse gases (IMG) instruments would be useful. Model development to better represent processes such as lightning, convection, pulsing of soil NO_x emissions, and uptake of HNO₃ on ice would improve the robustness of the constraint. Development of an adjoint model would provide a more formal approach to extend this analysis.

[45] **Acknowledgments.** We thank Folkert Boersma, Rynda Hudman, Ken Pickering, and three anonymous reviewers for helpful comments that

improved the manuscript. We are grateful to the Netherlands SCIAMACHY Data Center (NL-SCIA-DC) for providing data and processing services. This work was supported by NASA's Radiation Science Program.
